**Human endocrine system: A secreting organ or structure**

Parul

**Abstract**

The endocrine system and the changes of adolescence are two portions of the Core Knowledge study of the human body. We have combined the two as one mini-unit within the general topic of The Human Body, and have chosen to introduce the Endocrine System prior to Adolescent Changes in an attempt to make the latter information more valid and understandable for students.

**Keywords:** endocrine system, secreting organ, adolescence

**Introduction**

Simply put, endocrinology is the study of endocrine glands. Endocrine glands are a group of glands in the body which secrete hormones. The purpose of the secreted hormones is to cause a specific response in other cells of the body which are located far away. As shown in the picture, the hormones are secreted out of the cells of an endocrine gland into the bloodstream giving them access to all other cells of the body.

A great example of how hormones work is shown in our 5 minute video animation showing how a parathyroid gland grows into a tumor that secretes parathyroid hormone which then circulates through the bloodstream to cause lots of problems throughout the body. Remember, the definition of a hormone is a molecule that is secreted by one cell which has an effect on another cell some distance away.

**Types of Glands**

**Exocrine Gland**

Exocrine glands are glands that produce and secrete substances onto an epithelial surface by way of a duct. Examples of exocrine glands include sweat, salivary, mammary, ceruminous, lacrimal, sebaceous, and mucous. Exocrine glands are one of two types of glands in the human body, the other being endocrine glands, which secrete their products directly into the bloodstream. The liver and pancreas are both exocrine and endocrine glands; they are exocrine glands because they secrete products—bile and pancreatic juice—into the gastrointestinal tract through a series of ducts, and endocrine because they secrete other substances directly into the bloodstream.

**Endocrine Glands**

Endocrine glands are glands of the endocrine system that secrete their products, hormones, directly into the blood rather than through a duct. The major glands of the endocrine system include the pineal gland, pituitary gland, pancreas, ovaries, testes, thyroid gland, parathyroid gland, hypothalamus and adrenal glands. The hypothalamus and pituitary gland are neuroendocrine organs. Local chemical messengers, not generally considered part of the endocrine system, include autocrines, which act on the cells that secrete them, and paracrines, which act on a different cell type nearby.

The ability of a target cell to respond to a hormone depends on the presence of receptors, within the cell or on its plasma membrane, to which the hormone can bind. Hormone receptors are dynamic structures. Changes in number and sensitivity of hormone receptors may occur in response to high or low levels of stimulating hormones. Blood levels of hormones reflect a balance between secretion and degradation/excretion. The liver and kidneys are the major organs that degrade hormones; breakdown products are excreted in urine and feces. Hormone half-life and duration of activity are limited and vary from hormone to hormone.
The secretory organs that make up the human endocrine system, such as the anterior pituitary gland, the adrenal glands, and the pancreas, synthesize and secrete specific hormones. In addition, many endocrine glands, such as the thyroid gland, ovaries, and testes, are discrete, readily recognizable organs with defined borders and endocrine functions. Other glands are embedded within structures; for example, the islets of Langerhans are embedded within the pancreas and may be seen clearly only under the microscope.

### Glands and hormones of the human endocrine system

Hormones can be chemically classified into four groups:

- **Amino acid-derived**: Hormones that are modified amino acids.
- **Polypeptide and proteins**: Hormones that are chains of amino acids of less than or more than about 100 amino acids, respectively. Some protein hormones are actually glycoproteins, containing glucose or other carbohydrate groups.
Hormones circulating in the blood diffuse into the interstitial fluids surrounding the cell. Cells with specific receptors for a hormone respond with an action that is appropriate for the cell. Because of the specificity of hormone and target cell, the effects produced by a single hormone may vary among different kinds of target cells.

Hormones activate target cells by one of two methods, depending upon the chemical nature of the hormone.

Lipid-soluble hormones (steroid hormones and hormones of the thyroid gland) diffuse through the cell membranes of target cells. The lipid-soluble hormone then binds to a receptor protein that, in turn, activates a DNA segment that turns on specific genes. The proteins produced as result of the transcription of the genes and subsequent translation of mRNA act as enzymes that regulate specific physiological cell activity.

Water-soluble hormones (polypeptide, protein, and most amino acid hormones) bind to a receptor protein on the plasma membrane of the cell.

Cyclic AMP (CAMP) is produced when the receptor protein activates another membrane-bound protein called a G protein. The G protein activates adenylyl cyclase, the enzyme that catalyzes the production of CAMP from ATP. Cyclic AMP then triggers an enzyme that generates specific cellular changes.

Inositol triphosphate (IP3) is produced from membrane phospholipids. IP3, in turn, triggers the release of Ca2+ from the endoplasmic reticulum, which then activates enzymes that generate cellular changes.

Endocrine glands release hormones in response to one or more of the following stimuli:

- Hormones from other endocrine glands.
- Chemical characteristics of the blood (other than hormones).
- Neural stimulation.

Most hormone production is managed by a negative feedback system. The nervous system and certain endocrine tissues monitor various internal conditions of the body. If action is required to maintain homeostasis, hormones are released, either directly by an endocrine gland or indirectly through the action of the hypothalamus of the brain, which stimulates other endocrine glands to release hormones. The hormones activate target cells, which initiate physiological changes that adjust the body conditions. When normal conditions have been recovered, the corrective action - the production of hormones - is discontinued. Thus, in negative feedback, when the original (abnormal) condition has been repaired, or negated, corrective actions decrease or discontinue. For example, the amount of glucose in the blood controls the secretion of insulin and glucagons via negative feedback.

The production of some hormones is controlled by positive feedback. In such a system, hormones cause a condition to intensify, rather than decrease. As the condition intensifies, hormone production increases. Such positive feedback is uncommon, but does occur during childbirth, where hormone levels build with increasingly intense labor contractions. Also in lactation, hormone levels increase in response to nursing, which causes an increase in milk production. The hormone produced by the hypothalamus causing the milk let down and uterine contraction is oxytocin.

**Glossary**

**Adrenal Gland**: endocrine gland that is located on top of each kidney

**Amino Acid-derived**: hormones that are modified amino acids

**Antagonistic Hormones**: hormones that act to return body conditions to within acceptable limits from opposite extremes.

**Calcitonin**: hormone produced by the thyroid; contributes to the regulation of blood calcium levels.

**Eicosanoids**: lipids that are synthesized from the fatty acid chains of phospholipids found in plasma membrane.

**Endocrine Glands**: glands that have no duct and release their secretions directly into the intercellular fluid or into the blood.

**Endocrine System**: a control system of ductless glands that secrete chemical messengers called hormones.

**Estrogen**: hormone in females; stimulates the development of the uterus and vagina.

**Exocrine Glands**: glands that release their cellular secretions through a duct which empties to the outside or into the lumen (empty internal space) of an organ.

**Hormone**: a specific chemical substance produced by certain cells that control, or help to control, cellular processes elsewhere in an organism.

**Insulin**: hormone that acts to lower blood sugar levels by allowing the sugar to flow into cells.

**Iodine**: chemical in the body; Thyroid hormone cannot be produced without it.

**Lipid-soluble Hormones**: diffuse through the cell membranes of target cells.

**Parathyroid**: four masses of tissue, two embedded posterior in each lateral mass of the thyroid gland.

**Pancreas**: organ involved with the digestion system and the circulatory system; helps to maintain blood sugar levels.

**Pineal Gland**: small endocrine gland in the brain located near the center of the brain, between the two hemispheres, tucked in a groove where the two rounded thalamic bodies join.

**Platitary Gland**: endocrine gland that is attached to the hypothalamus of the lower forebrain.

**Polypeptide and Proteins**: hormones that are chains of amino acids of less than or more than about 100 amino acids.

**Steroids**: hormones that are lipids that are synthesized from cholesterol; characterized by four interlocking carbohydrate rings.

**Testosterone**: hormone more prominent in males; belongs to the family of androgens, which are steroid hormones producing masculinizing effects.

**Thyroid Gland**: endocrine gland that consists of two lateral masses that are attached to the trachea.

**Thyroxine**: serves to stimulate oxidative metabolism in cells; increases the oxygen consumption and heat production of most body tissues.

**Water-soluble Hormones**: bind to a receptor protein on the plasma membrane of the cell.
